Stabilization Policy and
the Costs of Dollarization[*]

Abstract

This paper compares the welfare costs of business cycles in a dollarized economy to those associated with several alternative monetary regimes belonging to three broad families: devaluation rate rules, inflation targeting, and money growth rate rules. The analysis is conducted within an optimizing model of a small open economy with sticky prices. The model is calibrated to the Mexican economy and is driven by three external shocks: terms of trade, world interest rate, and import-price inflation. We show econometrically that these shocks explain at a minimum 45 percent of the observed forecasting error variance of Mexican output and the Mexican real exchange rate at 8- to 16-quarter horizons. The model fits the data relatively well in the sense that it can account for the volatility and comovements of key macroeconomic indicators such as output, consumption, inflation, and the real exchange rate. The welfare comparisons suggest that dollarization is the least successful of the monetary policy rules considered: agents are willing to give up between 0.1 and 0.3 percent of their nonstochastic steady-state consumption to see a policy other than dollarization implemented. *JEL Classification Numbers:* F41, E58.

1   Introduction

The idea of replacing the domestic currency with the U.S. dollar is being debated actively in a number of emerging market economies. This is particularly the case in Argentina, Ecuador and Mexico, with Ecuador having taken the most concrete steps towards adoption of the dollar. Proponents of dollarization argue that by eliminating devaluation risk, dollarization will go a long way toward reducing country risk premia, thus lowering aggregate volatility. On the other hand, opponents of dollarization warn that this way of reducing country risk comes at a cost that may very well exceed its benefits. This paper contributes to the dollarization debate by examining one of its potential costs in detail.

At least three sources of costs associated with dollarization have been identified in the literature. One is the loss of seignorage revenue. When a country adopts the U.S. dollar as the sole legal tender, the stream of its seignorage revenue begins to flow to the U.S. central bank. Clearly, the magnitude of the cost of dollarization stemming from the loss of seignorage revenue for emerging market economies depends on their ability to negotiate a seignorage sharing agreement with the United States. In Schmitt-Grohé and Uribe (1999) we show that in the absence of a sharing agreement the amount of seignorage revenue lost due to dollarization is likely to be at least twice a country's pre-dollarization monetary base.

A second source of cost is the lack of a lender of last resort. Under dollarization, the government loses the ability to inject liquidity into the financial system in the event of a banking crisis through money creation. However, as pointed out by Calvo (1999a,b), domestic banks can have access to liquidity through a variety of sources other than the printing press of the central bank. Therefore, dollarization does not necessarily imply the loss of a lender of last resort but simply the disappearance of one particular source of liquidity, namely central bank credit.

A third source of costs arises from the fact that under dollarization a country relinquishes its ability to conduct cyclical monetary policy. In economies with nominal frictions, monetary policy can play an important role in stabilizing business cycles. To the extent that the shocks affecting the dollarized economy are different from those affecting the U.S. economy or affect the two economies asymmetrically, dollarization will come at the cost of higher macroeconomic instability. This is because U.S. monetary policy is likely to respond mainly to that country's state of the business cycle.

The purpose of this paper is to quantify the cost of dollarization arising from this third channel, that is, the reduced ability to accommodate asymmetric shocks. Specifically, we compare the level of welfare in a dollarized economy to the level of welfare in alternative economies that differ from a dollarized economy only in their monetary arrangements. The alternative monetary policy regimes we study belong to three broad families: (i) Devaluation-rate rules that set the devaluation rate as a function of the exogenous shocks driving business cycles; (ii) Inflation targeting which we take to imply that the central bank completely stabilizes the rate of inflation of either consumer or nontraded goods prices; and (iii) Money growth rate rules that stipulate a constant rate of expansion of the money supply.

The welfare-based evaluation of the alternative policy regimes involves five steps: the development of a utility-based theoretical framework that provides a metric for judging alternative policy specifications; the identification and estimation of the sources of aggregate fluctuations; the calibration of the structural parameters of the model; a comparison of

the predictions of the theoretical model to observed business-cycle regularities in Mexico; and the computation of the level of welfare associated with the alternative monetary policy arrangements.

The theoretical framework we use is an extension of a simpler one that has served as the workhorse in open economy macroeconomics since the seminal work of Calvo (1983). Specifically, we develop an optimizing dynamic general equilibrium model of a small open economy with endogenous labor supply and capital accumulation that produces exportables and nontradables and absorbs exportables, importables, and nontradables. In this framework, room for cyclical monetary policy arises from two sources: first, product prices in the nontraded sector are assumed to be sticky as in Rotemberg (1982). Second, there is a demand for money which originates from the assumption that real balances facilitate transactions in final goods as in Kimbrough (1986). These two sources of nominal rigidities create a tension for stabilization policy. On the one hand, the presence of sticky prices in the nontraded sector calls for policies that stabilize the nontraded component of CPI inflation. On the other hand, the fact that, via transaction costs, money acts as a tax on aggregate spending creates an incentive for the central bank to stabilize the opportunity cost of holding money, that is, the domestic nominal interest rate.

A recent literature on business cycles in emerging market economies has emphasized external shocks as the predominant source of aggregate fluctuations (Calvo, Leiderman, and Reinhart, 1993; Mendoza, 1995; Del Negro and Obiols-Homs, 1999). For example, Calvo, Leiderman, and Reinhart (1993) study the comovement between real exchange rates and U.S. interest rates for 10 Latin American countries between 1988 and 1992 and find that around half of the variance in real exchange rates can be explained by variations in U.S. interest rates. Mendoza (1995) presents a model-based evaluation of the contribution of terms-of-trade shocks to explaining output variability in developing countries and concludes that this type of shock accounts for around half of the variance of GDP. In a study of the Mexican economy, Del Negro and Obiols-Homs (1999) confirm these results by showing that over the period 1970 to 1997 most shocks to output and prices originated in the foreign sector in the form of shocks to U.S. industrial production, interest rates, and consumer and commodity prices. Based on this body of evidence, we focus on three external shocks as the principal sources of aggregate uncertainty: world-interest-rate, terms-of-trade, and world inflation shocks.

We estimate the stochastic processes followed by these three shocks using data from the Mexican economy. The estimated processes serve as the driving force of business cycles in our theoretical model. To gage the relative importance of the external shocks for observed Mexican business-cycle fluctuations, we perform a variance decomposition analysis of the Mexican real exchange rate and output. We find that more than 45 percent of the 8- to 16-quarter-ahead forecasting error variance of these two variables can be explained by our three external shocks.

We calibrate our model to the Mexican economy using long-run data restrictions for the post-debt-crisis era. We then compare observations on the comovements between key macroeconomic aggregates, such as output, consumption, investment, inflation, and the real exchange rate, over the period 1988-1994 to the predictions of the calibrated model to show that it explains Mexican business-cycle regularities well. Based on this result, we argue that the model economy studied in this paper is a relevant framework to evaluate the welfare

consequences for Mexico of dollarization and of other monetary regimes.

The analysis of the welfare costs for the Mexican economy of alternative monetary policy arrangements yields the following three results: first, the cost of business cycles during the Pacto period, 1988-1994, was about one third of one percent of the steady-state stream of consumption. This figure is comparable to that estimated by Lucas (1987) for the U.S. economy over a sample ending at the beginning of the Second World War. Lucas's welfare cost estimate is to a large extend the result of the fact that his prewar sample includes the Great Depression years, which were characterized by high aggregate volatility. By comparison, the welfare costs of business cycles during the Pacto era are more than three times as large as the upper bound that Lucas reports for the U.S. economy over the period following the Second World War.

Second, dollarization is more costly than any of the alternative nonestimated monetary policies considered. Consumers are willing to give up between one tenth and one third of one percent of their steady-state consumption to see a policy other than dollarization implemented.

Third, of the policies we consider, the best is one in which the central bank adopts a devaluation rate rule that stipulates an increase in the rate of devaluation in response to a rise in the world interest rate, a decline in the terms of trade, or a reduction in the inflation rate of imports. We find that the optimal rule within this class is "hyperactive" because it calls for a very large world interest rate coefficient of 26. An ad-hoc, conceivably more plausible specification with an interest rate coefficient of 2 still produces welfare costs significantly lower than those associated with dollarization. Taken at face value, the results of this paper provide a lower bound for the size of benefits that are required to make dollarization a socially viable proposal.

The remainder of the paper is organized in six sections. Section 2 presents the model, section 3 identifies the exogenous shocks generating aggregate fluctuations in Mexico and estimates their stochastic process. Section 4 describes the calibration of the structural parameters of the model. Section 5 compares the model's prediction regarding the relative volatility, correlation with output, and serial correlation of output, consumption, investment, and inflation to the actual comovements in these variables observed in Mexico over the period 1988-1994. Section 6 evaluates the welfare costs of Mexican business cycles under a number of different monetary stabilization policies and section 7 concludes the paper with a critical evaluation of the ability of dollarization to act as a commitment device.

2   A small open economy with sticky prices

We consider a small open economy with free access to international capital markets that produces two types of goods, exportables and nontradables, and absorbs three types of goods, exportables, importables, and nontradables. The economy features two sources of nominal rigidities. One originates in the nontraded sector, where production takes place under imperfectly competitive conditions and nominal prices adjust sluggishly. The other arises because purchases of final goods are assumed to be subject to a proportional transaction cost that is decreasing in the buyer's holdings of monetary balances relative to the value of his purchases. Business cycles are driven by exogenous, stochastic innovations in the terms

of trade, the world interest rate, and foreign inflation.

2.1 The private sector

The economy is populated by a large number of infinitely-lived households. Preferences are defined over processes of consumption, c_t, and labor effort, h_t, and are described by the following utility function:

$$E_0 \sum_{t=0}^{\infty} \beta^t U(c_t, h_t), \tag{1}$$

where E_t denotes the mathematical expectation conditional on information available in period t, $\beta \in (0,1)$ denotes the subjective discount factor, and U takes the particular form

$$U(c, h) = \frac{[c^\nu (1-h)^{1-\nu}]^{1-\sigma}}{1-\sigma}, \tag{2}$$

with $\sigma \geq 0$ and $\nu \in (0,1)$.

Households have access to two financial assets: domestic money, M_t, and a foreign-currency denominated bond, B_t, that pays the gross interest rate r_t between periods t and $t+1$. In addition, households can hold physical capital, k_t. Capital depreciates at the constant rate $\delta \in (0,1)$ per period and is subject to convex adjustment costs. Specifically, the law of motion of k_t is given by

$$k_{t+1} = (1-\delta)k_t + \phi\left(\frac{i_t}{k_t}\right) k_t, \tag{3}$$

where i_t denotes gross investment and ϕ is an increasing and concave function satisfying $\phi(\delta) = \delta$ and $\phi'(\delta) = 1$. We introduce capital adjustment costs to avoid the excess volatility of investment that typically arises in small open economy models (see Schmitt-Grohé, 1998).

Following Kimbrough (1986), domestic money demand is motivated by assuming that purchases of final goods are subject to a proportional transaction cost, $s(v_t)$, that is increasing in money velocity, v_t. In turn, velocity is defined as

$$v_t = \frac{p_t(c_t + i_t)}{m_t}, \tag{4}$$

where final goods prices, p_t, and real balances, m_t, are expressed in units of importable goods, that is, letting P_t and P_t^m be the price of final and importable goods in terms of domestic currency, $p_t \equiv P_t/P_t^m$ and $m_t \equiv M_t/P_t^m$.

Each household is the monopolistic supplier of a differentiated nontraded good. Following Rotemberg (1982), we introduce sluggish price adjustment in the nontraded sector by assuming that households face convex adjustment costs when they change the nominal price of the nontraded good they produce. The representative household's period-by-period budget constraint is given by

$$p_t(c_t + i_t)(1 + s(v_t)) + m_t + b_t + \tau_t \leq \frac{m_{t-1}}{\pi_t^m} + \frac{r_{t-1} b_{t-1}}{\pi_t^{m*}} + u_t k_t + w_t(h_t - \tilde{h}_t^n) + \tilde{p}_t^n F^n(\tilde{h}_t^n) - \theta(\tilde{\pi}_t^n). \tag{5}$$

The left-hand side of (5) represents the uses of wealth in period t expressed in terms of importables: consumption and investment purchases (including transaction costs), real balances, and real bond holdings, $b_t \equiv B_t/P_t^{m*}$, with P_t^{m*} denoting the foreign-currency price of importables, and real payments of lump-sum taxes, τ_t. The right-hand side of (5) represents the sources of wealth. Each period $t \geq 0$, the household starts with money balances carried over from the pervious period, whose real value is given by $M_{t-1}/P_t^m = m_{t-1}/\pi_t^m$, where $\pi_t^m \equiv P_t^m/P_{t-1}^m$ denotes domestic import price inflation. The household also receives the principal and interest on bonds acquired in period $t-1$ in the amount of $r_{t-1}b_{t-1}/\pi_t^{m*}$, where $\pi_t^{m*} \equiv P_t^{m*}/P_{t-1}^{m*}$ is the foreign import price inflation. The right-hand side of (5) also includes the household's current income, which consists of income from the rental of physical capital, wage earnings for hours worked outside the household, and sales of nontradables net of the cost of price adjustment. The variables u_t, w_t, and $\tilde{p}_t^n$ denote, respectively, the wage rate, the rental rate of capital, and the relative price of the differentiated good produced by the household, all expressed in terms of importables.

The function θ measures the cost of changing nominal prices and thus reflects the degree of nominal price stickiness. It is assumed to be strictly convex in the gross rate of inflation of the differentiated good produced by the household, $\tilde{\pi}_t^n \equiv \tilde{P}_t^n/\tilde{P}_{t-1}^n$, where $\tilde{P}_t^n$ denotes the domestic currency price of the good produced by the household. Note that $\tilde{\pi}_t^n$ can be written as:

$$\tilde{\pi}_t^n \equiv \frac{\tilde{p}_t^n}{\tilde{p}_{t-1}^n} \pi_t^m \tag{6}$$

We assume that $\theta(\pi^n) = 0$, where π^n denotes the nonstochastic steady-state inflation rate of nontradables, so that at this rate of inflation price stickiness imposes no resource costs on households. In addition, we require that $\theta'(\pi^n) = 0$, which implies, as will become clear shortly, that in the nonstochastic steady state households set prices so as to equate marginal cost to marginal revenue.

The technology used to produce the differentiated nontraded good takes the form $F^n(\tilde{h}_t^n) = \left(\tilde{h}_t^n\right)^\omega$, $0 < \omega < 1$. The variable $\tilde{h}_t^n$ denotes hours allocated to the production of the household's differentiated nontraded good. The household faces the demand function $q_t^n d(\tilde{p}_t^n/p_t^n)$, where q_t^n denotes the level of aggregate demand for nontradables, p_t^n is a price index of nontradables expressed in terms of importables, and d is a positive and decreasing function satisfying $d(1) = 1$ and $d'(1) < -1$. Such a demand function can be derived by assuming that final nontradable goods are a composite produced from differentiated intermediate goods via a Dixit-Stiglitz production function. The restriction imposed on $d'(1)$ is necessary for the household's price-setting problem to be well defined in a symmetric equilibrium. The individual household takes both q_t^n and p_t^n as given. Finally, we assume that households must set nominal prices one period in advance and that current output is demand determined, that is,

$$F^n(\tilde{h}_t^n) = q_t^n d\left(\frac{\tilde{p}_t^n}{p_t^n}\right) \tag{7}$$

The household chooses the set of stochastic processes $\{c_t, h_t, \tilde{h}_t^n, k_{t+1}, b_t, m_t, i_t, \tilde{p}_{t+1}^n, \tilde{\pi}_{t+1}^n\}_{t=0}^\infty$ so as to maximize (1) subject to (3)-(7) and some borrowing limit that prevents it from engaging in Ponzi-type schemes taking as given the sequences $\{p_t, p_t^n, q_t^n, u_t, w_t, r_{t-1}, \pi_t^m, \pi_t^{m*}\}_{t=0}^\infty$ and the initial conditions k_0, b_{-1}, $\tilde{p}_0^n$, and $\tilde{\pi}_0^n$. The associated first-order

conditions are

$$U_c(c_t, h_t) = \lambda_t p_t \left[1 + s(v_t) + v_t s'(v_t)\right] \tag{8}$$

$$-\frac{U_h(c_t, h_t)}{U_c(c_t, h_t)} = \frac{w_t}{p_t}\left[1 + s(v_t) + v_t s'(v_t)\right]^{-1} \tag{9}$$

$$\lambda_t = \beta E_t \lambda_{t+1}\left(\frac{r_t}{\pi_{t+1}^{m*}}\right) \tag{10}$$

$$1 - v_t^2 s'(v_t) = \beta E_t \left(\frac{\lambda_{t+1}}{\lambda_t} \frac{1}{\pi_{t+1}^m}\right) \tag{11}$$

$$p_t\left[1 + s(v_t) + v_t s'(v_t)\right] = \mu_t^k \phi'\left(\frac{i_t}{k_t}\right) \tag{12}$$

$$\mu_t^k = \beta E_t \frac{\lambda_{t+1}}{\lambda_t}\left\{u_{t+1} + \mu_{t+1}^k\left[1 - \delta + \phi\left(\frac{i_{t+1}}{k_{t+1}}\right) - \phi'\left(\frac{i_{t+1}}{k_{t+1}}\right)\frac{i_{t+1}}{k_{t+1}}\right]\right\} \tag{13}$$

$$E_t \lambda_{t+1} \theta'(\tilde{\pi}_{t+1}^n)\tilde{\pi}_{t+1}^n = \beta E_t \lambda_{t+2} \theta'(\tilde{\pi}_{t+2}^n)\tilde{\pi}_{t+2}^n + E_t \lambda_{t+1} F^n(\tilde{h}_{t+1}^n)\frac{mr_{t+1} - mc_{t+1}}{mr_{t+1}/\tilde{p}_{t+1}^n - 1} \tag{14}$$

The variable λ_t is the Lagrange multiplier on the budget constraint (5) and represents the marginal utility of wealth in terms of importables. The right-hand side of equation (11) is the reciprocal of the gross nominal interest rate on domestic risk-free bonds. Equation (11) therefore implies that money velocity is determined solely by the nominal interest rate and is strictly increasing in this variable. Equations (9) and (12) show that the opportunity cost of holding money acts as a tax on both effort and investment. The variable $\mu_t^k \lambda_t$ is the Lagrange multiplier on the law of motion of physical capital, equation (3). Thus μ_t^k represents the shadow price of installed capital in terms of importables, or Tobin's Q. Equation (12) then says that gross investment is increasing in Tobin's Q. In equation (14), mr_t and mc_t denote, respectively, marginal revenue and marginal cost, which are defined as

$$mr_t = \tilde{p}_t^n\left[1 + \frac{d\left(\frac{\tilde{p}_t^n}{p_t^n}\right)}{d'\left(\frac{\tilde{p}_t^n}{p_t^n}\right)\frac{\tilde{p}_t^n}{p_t^n}}\right] \tag{15}$$

$$mc_t = \frac{w_t}{F^{n'}(\tilde{h}_t^n)} \tag{16}$$

Hence equation (14) shows that the presence of nominal rigidities induces the firm to deviate from equating marginal cost to marginal revenue.

Final goods are assumed to be a composite of nontradable, exportable, and importable goods produced with a technology of the form

$$q_t^f = F^f(a_t^n, a_t^x, a_t^m), \tag{17}$$

where a_t^n, a_t^x, and a_t^m denote, respectively, domestic absorption of nontradable, exportable, and importable goods in period t. The production technology is assumed to be of the form $F^f(a^n, a^x, a^m) = (a^n)^{\alpha^n}(a^x)^{\alpha^x}(a^m)^{\alpha^m}$, with $\alpha^i > 0$ for $i = n, x, m$ and $\alpha^n + \alpha^x + \alpha^m = 1$.

The market for final goods is perfectly competitive and prices are fully flexible. Thus, the representative firm's demands for inputs satisfy

$$p_t F_n^f(a_t^n, a_t^x, a_t^m) = p_t^n \tag{18}$$

$$p_t F_x^f(a_t^n, a_t^x, a_t^m) = p_t^x \tag{19}$$

$$p_t F_m^f(a_t^n, a_t^x, a_t^m) = 1, \tag{20}$$

where F_i^f denotes the partial derivative of F^f with respect to a^i for $i = n, x, m$ and $p_t^x \equiv P_t^x/P_t^m$ denotes the relative price of exportables in terms of importables, or the terms of trade.

Like the final goods producing sector, the sector producing export goods is perfectly competitive and prices are fully flexible. Exportable output, q_t^x, is produced using capital, k_t, and labor services, h_t^x, according to the following technology:

$$q_t^x = F^x(k_t, h_t^x), \tag{21}$$

where $F^x(k, h) = k^{\alpha^k} h^{1-\alpha^k}$, $0 < \alpha^k < 1$. Each period, firms choose capital and labor services so as to maximize profits, which are given by $p_t^x F^x(k_t, h_t^x) - u_t k_t - w_t h_t^x$. Input demands must then satisfy the following efficiency conditions:

$$p_t^x F_k^x(k_t, h_t^x) = u_t \tag{22}$$

and

$$p_t^x F_h^x(k_t, h_t^x) = w_t. \tag{23}$$

2.2 The government

2.2.1 Monetary Policy

The goal of this paper is to study the business-cycle implications for Mexico of a number of alternative monetary arrangements. At center stage is the case of dollarization. Abstracting from its implications for seignorage revenue and shoe-leather costs, dollarization can be interpreted as a perfectly credible peg of the devaluation rate. Accordingly, we model dollarization as

$$\epsilon_t = \bar{\epsilon} \qquad \forall t, \tag{24}$$

where ϵ_t denotes the gross rate of devaluation of the domestic currency and is given by $\mathcal{E}_t/\mathcal{E}_{t-1}$, where $\mathcal{E}_t$ denotes the nominal exchange rate, defined as the price of one US dollar in terms of Mexican pesos.

In addition to dollarization, we consider five monetary specifications. The first is one in which the central bank directly controls the monetary aggregate by setting the growth rate of the money supply. Specifically, we consider simple rules of the type

$$M_t = (1 + \zeta)M_{t-1}, \tag{25}$$

where ζ is the rate of expansion of the money supply. Under this policy the nominal exchange rate floats freely, thus it is often regarded as the polar case to dollarization.

7

The second alternative monetary policy regime we consider is inflation targeting. This kind of policy has recently been advocated, on theoretical grounds, by a number authors, notably Svensson (1997, 1999), and has been put into practice by central banks in several countries, such as New Zealand and Australia. We assume that inflation targeting takes the form of a constant CPI inflation rate.[1] Letting $\pi_t \equiv P_t/P_{t-1}$ denote gross CPI inflation and $\bar{\pi}$ the inflation target, inflation targeting takes the form

$$\pi_t = \bar{\pi} \qquad \forall t. \tag{26}$$

Third, we study the stabilizing properties of a monetary policy that eliminates all inefficiencies stemming from nominal price rigidities. Specifically, we will analyze a policy that ensures that in the nontraded sector marginal cost equals marginal revenue at all times and under all circumstances:

$$mr_t = mc_t \tag{27}$$

If one restricts attention to small fluctuations around the non-stochastic steady state, as we do throughout our analysis, this policy regime implies that the government completely stabilizes future inflation of nontradables, $\pi_{t+1}^n = \bar{\pi}^n$, $\forall t \geq 0$, where $\bar{\pi}^n$ is some constant inflation target (recall that π_{t+1}^n is in the information set of period t).[2]

Fourth, we investigate the dynamic properties of devaluation-rate rules whereby the rate of devaluation of the domestic currency is set as a linear function of the exogenous variables driving business cycles in the economy under consideration, namely, the terms of trade, import price inflation, and the world interest rate. That is,

$$\widehat{\epsilon}_t = \alpha^{p^x}\widehat{p}_t^x + \alpha^{\pi^m}\widehat{\pi}_t^{m*} + \alpha^r \widehat{r}_t^*, \tag{28}$$

where $\widehat{x}_t \equiv \ln(x_t/\bar{x})$ denotes the log-deviation of x_t from its nonstochastic steady-state value $\bar{x}$. The coefficients α^i, $i = p^x, \pi^m, r$ are chosen so as to minimize the welfare costs of business cycles. The choice of the left-hand-side variable in the above monetary policy rule is meant to reflect the fact that in developing countries, and particularly in Latin America, policymakers have traditionally favored the devaluation rate as the monetary policy instrument (see Kiguel and Liviatan, 1992, and the references cited therein).

Finally, we consider the following stochastic version of (24)

$$\epsilon_t = \bar{\epsilon}e^{\eta_t^\epsilon}, \tag{29}$$

where η_t^ϵ is a mean-zero i.i.d. shock. As we argue below, this type of rule describes Mexican monetary policy during the period 1988:Q2-1994:Q3 over which the exchange-rate stabilization program known as the Pacto de Solidaridad Económica was in place. We are particularly interested in this period of Mexican economic history because it represents a relatively long span of time over which monetary policy was fairly homogenous. We use the Pacto era both as the calibration period for our baseline model and as a point of reference to assess the model's ability to account for actual Mexican fluctuations.

---

[1]Calvo (1979) finds that inflation targeting renders the rational expectations equilibrium indeterminate. This is not the case in our model. Two important elements distinguish our theoretical framework from Calvo's: the presence of sticky prices and the fact that money affects aggregate activity through aggregate demand rather than aggregate supply.

[2]However, a policy that ensure that $\pi_{t+1}^n = \bar{\pi}^n$ $\forall t \geq 0$ does not imply (27).

2.2.2 Fiscal Policy

For simplicity, we assume that government consumption and government bond holdings are zero at all times. In this case, the consolidated government budget constraint can be written as

$$\tau_t = m_t - \frac{m_{t-1}}{\pi_t^m}. \tag{30}$$

The assumed fiscal policy implies that the government rebates seignorage revenues to the public through lump-sum transfers.

2.3 Equilibrium

In a symmetric equilibrium, all firms in the nontraded goods sector set identical prices and quantities, so that $\tilde{p}_t^n = p_t^n$, $\tilde{h}_t^n = h_t^n$, and $\tilde{\pi}_t^n = \pi_t^n$. The definition of inflation of nontradables given in (6) then implies that

$$\pi_t^n = \frac{p_t^n}{p_{t-1}^n}\pi_t^m \tag{31}$$

In turn, equations (7) and (14)-(16) can be written as:

$$q_t^n = F^n(h_t^n) \tag{32}$$

$$
\begin{aligned}
E_t\lambda_{t+1}\theta'(\pi_{t+1}^n)\pi_{t+1}^n &= \beta E_t\lambda_{t+2}\theta'(\pi_{t+2}^n)\pi_{t+2}^n \\
&\quad -\frac{1+\mu}{\mu}E_t\lambda_{t+1}q_{t+1}^n\left[mr_{t+1} - mc_{t+1}\right],
\end{aligned} \tag{33}
$$

$$mr_t = \frac{p_t^n}{1+\mu}, \tag{34}$$

and

$$mc_t = \frac{w_t}{F^{n'}(h_t^n)}, \tag{35}$$

where $1+\mu \equiv d'(1)/(1+d'(1))$ is the steady-state markup of prices over marginal cost in the nontraded sector. Market clearing in the labor, nontraded, and final goods markets implies that:

$$h_t = h_t^x + h_t^n \tag{36}$$

$$q_t^n = a_t^n \tag{37}$$

$$q_t^f = (c_t + i_t)(1 + s(v_t)) \tag{38}$$

In equilibrium, the stock of foreign bonds evolves according to the following equation:

$$b_t = \frac{r_{t-1}}{\pi_t^{m*}}b_{t-1} + tb_t, \tag{39}$$

where tb_t denotes the trade balance in units of importables in period t and is given by

$$tb_t = p_t^x(q_t^x - a_t^x) - a_t^m \tag{40}$$

9

We assume that the law of one price holds for tradable goods, that is, the domestic prices of importables and exportables, P_t^m and P_t^x, are linked to the respective world prices, P_t^{m*} and P_t^{x*}, by the relationships $P_t^x = \mathcal{E}_t P_t^{x*}$ and $P_t^m = \mathcal{E}_t P_t^{m*}$. The domestic economy takes world prices as exogenous. The first of the above relationships implies that domestic import price inflation equals the sum of foreign import price inflation and the devaluation rate, that is,

$$\pi_t^m = \epsilon_t \pi_t^{m*} \tag{41}$$

Consumer price inflation is defined as

$$\pi_t = \frac{p_t}{p_{t-1}} \pi_t^m \tag{42}$$

Finally, we assume that the nominal interest rate at which the country can borrow internationally is given by the world interest rate plus a premium. The size of the interest rate premium is assumed to be increasing in the country's stock of foreign debt. Specifically, the gross interest rate on foreign-currency denominated bonds is given by

$$r_t = r_t^* \rho(-b_t), \tag{43}$$

where r_t^* denotes the gross world interest rate and is taken as exogenous by the country, and ρ is a positive and increasing function. The reason for introducing a debt elastic interest rate premium is technical. As is well known, small open economies that face a purely exogenous world interest rate display nonstationary dynamics in response to stationary exogenous shocks. As a result, the solution to the log-linearized equilibrium conditions may not be a valid approximation to the exact, nonlinear equilibrium system. Since we wish to employ log-linear solution methods to characterize the equilibrium dynamics, we must eliminate any source of nonstationarity. One way to do so is to assume a variable interest rate premium as in (43). To ensure that at business-cycle frequencies the model behaves as if the interest rate premium was constant, in the numerical experiments we set the debt elasticity of the interest rate premium very close to zero.

We define a stationary rational expectations equilibrium under dollarization as a set of stationary stochastic processes $\{v_t, p_t, c_t, i_t, m_t, h_t, \lambda_t, \mu_t^k, w_t, u_t, q_t^x, k_{t+1}, h_t^x, q_t^f, h_t^n, tb_t, b_t, a_t^x, a_t^m, a_t^n, q_t^n, p_t^n, \pi_{t+1}^n, \epsilon_t, r_t, \pi_t^m, \pi_t, mr_t, mc_t\}_{t=0}^\infty$ satisfying (3)-(4), (8)-(13), (17)-(29), and (31)-(43), given exogenous processes $\{\pi_t^{m*}, p_t^x, r_t^*, \}_{t=0}^\infty$ and initial conditions k_0, b_{-1}, π_0^n, r_{-1}, and p_{-1}^n. Equilibrium under any of the alternative monetary policy regimes discussed above can be defined in a similar manner by replacing in the above definition equation (24) with the appropriate monetary specification.

Two macroeconomic indicators we will focus on are the real exchange rate and GDP. GDP is defined as the value of all goods produced in the economy in terms of final goods; formally,

$$gdp_t = \frac{p_t^x q_t^x + p_t^n q_t^n}{p_t}$$

The real exchange rate is defined as the relative price of tradables in terms of consumption. Letting p_t^T denote the relative price of tradables in terms of import goods, we have that the

real exchange rate, e_t is given by[3]

$$e_t = \frac{p_t^T}{p_t}$$

We characterize the equilibrium dynamics by solving a calibrated, log-linear approximation to the equilibrium conditions around the nonstochastic steady state. The calibration exercise involves two tasks. One is the estimation of the stochastic process of the exogenous shocks representing the sources of aggregate fluctuations. The second is the use of long-run data and model restrictions to identify the deep structural parameters of the model.

3 Sources of aggregate fluctuations in the Mexican economy

We now turn to the estimation of the law of motion of the three external sources of uncertainty driving business cycles in our model economy: the terms of trade, the world interest rate, and import price inflation. As mentioned earlier, our choice of shocks is guided by the results of a number of recent studies pointing at the fact that external shocks explain a significant fraction of aggregate fluctuations in developing countries in general (Calvo, Leiderman, and Reinhart, 1993) and in Mexico in particular (Del Negro and Obiols-Homs, 1999). In this section, we provide evidence corroborating the results of these studies. Specifically, we estimate the share of the k-quarter-ahead forecasting error variance in Mexican value added and the Mexican real exchange rate that is explained by our three foreign shocks.

The empirical model is a vector auto regression in the cyclical components of the logarithms of the terms of trade, $\widehat{p}_t^x$, gross import price inflation, $\widehat{\pi}_t^{m*}$, gross world nominal interest rates, $\widehat{r}_t^*$, real gross domestic product, $\widehat{y}_t$, and the Peso/dollar real exchange rate, $\widehat{e}_t$. Our sample consists of quarterly observations beginning in the first quarter of 1987 and ending in the second quarter of 1999. We measure the terms of trade as the ratio of dollar export prices to dollar import prices for Mexico. Our measure of import-price inflation is the 3-month geometric mean of the monthly change in the dollar import price index of Mexico. The world nominal interest rate is taken to be the constant maturity yield on 3-month U.S. Treasury bills. Mexican real output is measured by gross domestic product at constant 1993 prices. The real exchange rate is measured as the ratio of the U.S. CPI index to the corresponding Mexican index adjusted by the nominal exchange rate.[4]

The evolution of the external shocks is assumed to be exogenous to the Mexican economy. In addition, we assume that innovations to import price inflation do not affect the terms of trade contemporaneously and that innovations to the 3-month Treasury bill rate have no contemporaneous effect on either Mexican terms of trade or Mexican import price inflation. These identification assumptions give rise to the following block recursive structure of the

---

[3]One can show that $p^T = p^x/G_x(a^x, a^m)$ and $G(a^x, a^m) \equiv (a^x)^{\frac{\alpha^x}{\alpha^x + \alpha^m}} (a^m)^{\frac{\alpha^m}{\alpha^x + \alpha^m}}$.

[4]The data source for the dollar export and import price indices for Mexico and Mexican GDP is INEGI; the Mexican peso-U.S. dollar exchange rate and the Mexican CPI were obtained from Banco de Mexico; the U.S. CPI was taken from the Bureau of Labor Statistics; and the 3-month Treasury bill rate from the Board of Governors of the Federal Reserve System.

empirical model:

$$
\begin{bmatrix} \mathbf{a}_{11} & \mathbf{0}_{3\times 2} \\ \mathbf{a}_{21} & \mathbf{a}_{22} \end{bmatrix}
\begin{pmatrix} \widehat{p}_t^x \\ \widehat{\pi}_t^{m*} \\ \widehat{r}_t^* \\ \widehat{y}_t \\ \widehat{e}_t \end{pmatrix}
=
\begin{bmatrix} \mathbf{b}_{11}(L) & \mathbf{0}_{3\times 2} \\ \mathbf{b}_{21}(L) & \mathbf{b}_{22}(L) \end{bmatrix}
\begin{pmatrix} \widehat{p}_{t-1}^x \\ \widehat{\pi}_{t-1}^{m*} \\ \widehat{r}_{t-1}^* \\ \widehat{y}_{t-1} \\ \widehat{e}_{t-1} \end{pmatrix}
+
\begin{pmatrix} \epsilon_t^{p^x} \\ \epsilon_t^{\pi^{m*}} \\ \epsilon_t^{r^*} \\ \epsilon_t^y \\ \epsilon_t^e \end{pmatrix}, \qquad (44)
$$

where $\mathbf{a}_{11}$ and $\mathbf{a}_{22}$ are lower triangular matrices whose diagonal elements are equal to 1. The disturbance vector $(\epsilon_t^{p^x}, \epsilon_t^{\pi^{m*}}, \epsilon_t^{r^*}, \epsilon_t^y, \epsilon_t^e)$ has mean zero and diagonal variance/covariance matrix $\boldsymbol{\Sigma}$.

Based on a likelihood ratio test, we include four lags in the vector autoregression. All equations include a constant and a linear trend. The output and real exchange rate equations include, in addition, seasonal dummies and dummies meant to reflect exchange-rate regime changes. Specifically, a number of authors have identified several exchange rate regime shifts in Mexico over the sample period we are considering. They find that these regime shifts have typically been associated with substantial macroeconomic volatility. For example, Del Negro and Obiols-Homs identify three distinct exchange-rate regimes since the debt crisis of the early 1980s: the period 1982:Q4-1987:Q4 was characterized by a dual exchange rate regime with a pre-announced schedule for the official exchange rate; the period 1988:Q2-1994:Q3 as mentioned above corresponds to the Pacto de Solidaridad Económica; and the collapse of the Pacto in December of 1994 was followed by a dirty float. Because our sample begins in 1987, which is near the end of the dual exchange rate regime, we address the regime shift problem by including only one level dummy marking the dirty float in the equations describing the evolution of real GDP and the real exchange rate. The external bloc of the VAR system, formed by the first three equations of (44), serves as the driving force of aggregate fluctuations in the theoretical model. Table A1 in the appendix presents the estimated coefficients of this bloc.

Table 1 shows the fraction of the k-quarter ahead forecasting error variance of output and

Table 1: Variance Decomposition of Mexican Output and Real Exchange Rate
Sample: 1987:Q1 to 1999:Q2

| k | Percent of k-quarter ahead forecasting error variance explained by external and domestic disturbances | | | |
| | Output | | Real Exchange Rate | |
	external shocks	domestic shocks	external shocks	domestic shocks
4	26	74	35	65
8	45	55	44	56
12	64	36	46	54
16	68	32	47	53

the real exchange rate explained by the three external shocks and the two domestic shocks.

12

At a horizon of 8 quarters, about half of the forecasting error variance of output is due to external shocks. At horizons of 3 years or longer, the fraction of forecasting error variance of output explained by external shocks is around 2/3. External shocks explain about half of the variance of the real exchange rate forecasting errors at horizons of 8 quarters or longer. We interpret these results as suggesting that in Mexico over the past 12 years, the three external shocks that are assumed to drive business cycles in our theoretical model explain a large fraction of the observed aggregate fluctuations in Mexico at business-cycle frequencies.

Of the three external shocks we consider, the world interest rate plays the most important role in explaining output fluctuations. At all horizons, innovations in the world interest rate account for more than half of the forecasting error variance of Mexican output explained by external shocks. At the same time, both the world interest rate and terms of trade appear to be important determinants of the observed movements in the real exchange rate. At all horizons, about half of the variance of forecasting errors due to external shocks is attributable to terms of trade shocks and one third to world interest rate shocks.

4   Calibration

We calibrate the model to the Mexican economy. The log-linear approximation to the equilibrium conditions involves 16 free parameters, whose assigned values are presented in table 2, and 17 implied parameters, whose values are shown in table 3.   The time unit is chosen to be a quarter. Following Mendoza and Uribe (1999), we set the share of traded value added in GDP to 44.2 percent, the investment share in GDP to 21.7 percent, the trade balance share in GDP to 3.6 percent, the labor share in the traded sector to 26.1 percent, the labor share in the nontraded sector to 35.9 percent, the average world real interest rate to 6.5 percent per year, and the labor-leisure ratio to 0.25. We use the money demand estimates for Mexico presented in Kamin and Rogers (1996) to set the log-log interest elasticity of money demand to -0.16. The steady-state GDP velocity was set at 3.92 per quarter, which corresponds to the average of the ratio of nominal GDP to nominal M1 over the Pacto era. The steady-state devaluation rate was set at 1.57 percent per quarter, which corresponds to the average devaluation rate of the Mexican peso/US dollar exchange rate observed over the period 1988:2-1994:3. We assign a value of 24.0 percent to the share of exports to GDP, to match the average of this ratio in the Mexican economy over the period 1993-1999. The consumption elasticity of the marginal utility of consumption was set to -5 drawing on an empirical study by Reinhart and Végh (1995).

There is little empirical evidence on the degrees of imperfect competition and price stickiness in developing countries and in particular in the Mexican economy. Thus, as a first pass, we set the average markup of price over marginal cost in the nontraded sector to 10 percent, which is consistent with estimates for the U.S. economy (e.g., Basu and Fernald, 1997). To calibrate the degree of price stickiness, we use Sbordone's (1998) estimate of a linear new-Keynesian Phillips curve. Such a Phillips curve arises in our model from a log-linearization of equilibrium condition (33):

$$E_t\widehat{\pi}_{t+1}^n = \beta E_t\widehat{\pi}_{t+2}^n - \frac{1}{\eta_\theta\mu}(E_t\widehat{p}_{t+1}^n - E_t\widehat{mc}_{t+1}),$$

Table 2: Calibrated parameters

Symbol	Definition	Value	Description
s_x	$\frac{p^x q^x}{p\,GDP}$	0.442	share of traded value added in GDP
s_{tb}	$\frac{p^x(q^x-a^x)-a^m}{p\,GDP}$	0.036	trade balance to GDP ratio
s_{xx}	$\frac{p^x(q^x-a^x)}{p\,GDP}$	0.240	export share in value added
$\frac{r}{\pi^m}$		1.065	gross annual world real interest rate
ϵ		1.0157	gross quarterly devaluation rate
s_{hx}	$\frac{wh^x}{p^x q^x}$	0.261	labor share in exportable sector
s_{hn}	$\frac{wh^n}{p^n q^n}$	0.359	labor share in nontraded sector
η_{mi}	$\frac{\partial \ln m}{\partial \ln \frac{i}{1+i}}$	-0.16	log-log interest elasticity of money demand
s_i	$\frac{(1+s(v))pi}{p\,GDP}$	0.217	investment share in GDP
$\eta_{\phi\phi}$	$\frac{\phi''(\delta)\delta}{\phi'(\delta)}$	-0.13	minus elasticity of Tobin's Q w.r.t. investment
μ	$\frac{p^n-mc}{mc}$	0.1	markup of prices over marginal cost in the nontraded sector
η_θ	$\frac{\theta''(0)\pi^2}{\lambda p^n q^n}$	175	markup coefficient in new-Keynesian Phillips curve
v_{GDP}	$\frac{P\cdot GDP}{M1}$	3.92	quarterly GDP money velocity
$\frac{h}{1-h}$		0.25	steady state labor-to-leisure ratio
η_{cc}	$\frac{U_{CC}C}{U_C}$	-5	elasticity of marginal utility of consumption with respect to consumption
η_ρ	$\frac{\partial \ln r_t}{\partial \ln(-b_t)}$	10^{-5}	debt elasticity of country interest rate premium

where η_θ is a positive parameter increasing in $\theta''(\pi^n)$. Using U.S. data, Sbordone finds that $\eta_\theta\mu$ equals 17.5, which, given our assumption that $\mu = 0.1$, implies that η_θ equals 175. As pointed out by Sbordone, in a Calvo-Yun staggered price setting model, this value of η_θ implies that firms change their price on average every 9 months. In the context of our model, this calibration of the degree of price stickiness implies that in response to a once-and-for-all devaluation of the Mexican peso, the adjustment of the Mexican CPI achieves 42 percent of its long-run adjustment in the first quarter and 91 percent after 4 quarters.

We set the elasticity of Tobin's Q with respect to investment at 0.13, so as to match the observed volatility of investment of 12 percent over the Pacto era. In computing the volatility of investment predicted by the theoretical model, we use our estimate of Mexican monetary policy over the Pacto era, which is presented in the next section. Finally, we assume that the debt elasticity of the country premium is equal to 10^{-5}. As explained earlier, we pick such a small number to ensure that at business-cycle frequencies the economy behaves as if the country premium was constant.

Table 3: Implied parameters

Symbol	Definition	Restriction	Value	Description
β		π^m/r	0.9844	discount factor
s_n	$\frac{p^n q^n}{pGDP}$	$1-s_x$	0.558	share of nontraded value added in GDP
s_{kx}	$\frac{uk}{p^x q^x}$	$1-s_{hx}$	0.739	capital share in the traded sector
s_h	$\frac{wh^x+wh^n}{pGDP}$	$s_{hx}s_x + s_{hn}s_n$	0.316	labor share in GDP
s_c	$\frac{(1+s(v))pc}{pGDP}$	$1-s_i-s_{tb}$	0.747	consumption-to-GDP ratio
γ	$s(v)\equiv Av^\gamma$	$-\frac{1+\eta_{mi}}{\eta_{mi}}$	5.25	velocity elasticity of transaction cost
v	$\frac{p(c+i)}{m}$	$(1-s_{tb})v_{GDP} - \frac{r\epsilon-1}{r\epsilon\gamma}$	3.77	absorption velocity of money
A	$s(v)=Av^\gamma$	$\frac{(r\epsilon-1)}{r\epsilon\gamma v^{1+\gamma}}$	1.46×10^{-6}	scale factor in transaction cost function
δ		$\frac{(r/\pi^m-1)s_i}{\frac{s_{kx}(1+s(v))}{[1+s(v)+vs'(v)]}-s_i}$	0.129	annual capital depreciation rate
ν		$\frac{1}{1+\frac{1-h}{h}\frac{s_h(1+s(v))}{s_c[1+s(v)+vs'(v)]}}$	0.374	preference parameter (see eqn. 2)
σ		$1-\frac{1+\eta_{cc}}{\nu}$	11.71	preference parameter (see eqn. 2)
α^n	$\frac{F_n^f a^n}{F^f}$	$\frac{1-s_x}{1-s_{tb}}$	0.579	elasticity of F^f w.r.t. a^n
α^x	$\frac{F_x^f a^x}{F^f}$	$\frac{s_x-s_{xx}}{1-s_{tb}}$	0.210	elasticity of F^f w.r.t. a^x
α^m	$\frac{F_m^f a^m}{F^f}$	$\frac{s_{xx}-s_{tb}}{1-s_{tb}}$	0.211	elasticity of F^f w.r.t. a^m
ω	$\frac{F^{n'}h^n}{F^n}$	$s_{hn}(1+\mu)$	0.395	elasticity of F^n w.r.t. h^n
α^k	$\frac{F_k^x k^x}{F^x}$	s_{kx}	0.739	elasticity of F^x w.r.t. k^x
$1-\alpha^k$	$\frac{F_h^x h^x}{F^x}$	s_{hx}	0.261	elasticity of F^x w.r.t. h^x

5   Actual and predicted comovements

We compare the aggregate comovements implied by the model to those observed in Mexico during the Pacto era (1988:Q2-1994:Q3). We choose this period because it is characterized by a fairly homogeneous monetary policy regime. Specifically, during the Pacto era, the Mexican government followed a managed exchange rate regime. Although, as pointed out by Santaella and Vela (1996), the management of the exchange rate during the Pacto took a number of different forms, including subperiods with a fixed exchange rate, a preannounced rate of devaluation, and an exchange rate band, on net the rate of devaluation exhibited a fairly stable behavior. Indeed in the literature on disinflation in developing countries, the Pacto is considered a prime example of orthodox exchange-rate-based stabilization (see Rebelo and Végh, 1995 and the references cited therein). We model the behavior of the devaluation rate during the Pacto era as following an i.i.d. process like the one described in equation (29). Our estimate of that specification yields:

$$\ln \epsilon_t = 0.0157 + \eta_t^\epsilon; \quad \sigma_{\eta^\epsilon} = 0.0145.$$

The estimated value of σ_{η^ϵ} is small compared to the standard deviation of the devaluation rate observed in the pre- and post-Pacto years. The standard deviation of ϵ_t was 0.1154

during the period 1976:1-1988:1 and 0.1043 during the period 1994:4-1999:3.

To compute the comovement among key macroeconomic variables, we feed the above monetary policy and the estimated process for the external variables given in table A1 into the calibrated and log-linearized version of the model presented in section 2. We then construct artificial time series of length 500 using nonstochastic steady-state values as initial conditions. We compute sample second moments from the last 26 observations of each artificial time series. Thus, implied second moments are computed from time series that have the same length in quarters as the ones used in calculating observed second moments.[5] We repeat this procedure 1000 times and calculate the average of the sample second moments. The cyclical components of actual data are measured as deviations from a log-linear time trend.[6] Second moments for all variables were computed using the 26 observations of the Pacto era.

In our model economy consumption is a nondurable good. However, for the Pacto era, only data on total consumption expenditures is available, which includes expenditures on consumer durables as well as on nondurables and services. Consumption of durable goods is significantly more volatile than that of nondurables and services. For example, in the period 1993:1-1999:2, for which disaggregated consumption data is available, the ratio of the variance of nondurables and services to the variance of total consumption was 0.52. We approximate the standard deviation of nondurable consumption during the Pacto era by the product of this ratio and the standard deviation of total consumption.[7]

Table 4 presents the comovements of output, consumption, investment, CPI inflation, the trade balance share, and the real exchange rate observed in the Mexican economy during the Pacto era and those predicted by the theoretical economy. The model is broadly consistent with the data. Specifically, it captures well the volatility of output, consumption, and inflation, but slightly overpredicts the volatility of the trade-balance-to-GDP ratio and underpredicts the volatility of the real exchange rate.[8] In addition, the model correctly implies that consumption, investment and inflation are positively correlated with output and that the trade balance share is acyclical. The main counterfactual prediction of the model concerns the cyclical behavior of the real exchange rate. In the data this variable is uncorrelated with output, whereas the model predicts a large positive correlation. Overall, our model can capture the comovements of macroeconomic aggregates in the Pacto era fairly accurately. This finding is of great importance for it gives relevance to the welfare comparisons

---

[5]This approach implicitly assumes that the same monetary policy prevailed before and during the Pacto era, which is clearly counterfactual. We obtain similar results if, instead, we construct time series of length 26 using the nonstochastic steady-state values as initial conditions.

[6]In constructing the trend of output, consumption, and investment we used the longest quarterly sample available, 1980:1-1999:2. The real exchange rate, inflation, and the trade balance-to-output ratio were detrended using the Pacto sample period. The reason for using a shorter sample in detrending these variables is that, as stressed by the supply-side explanations of the real effects of exchange-rate-based stabilization (Rebelo, 1993, Uribe, 1997, 2000), permanent reductions in inflation expectations, like the one that arguably took place in Mexico at the beginning of the Pacto era, are associated with a gradual adjustment in these variables to new long-run levels.

[7]Note that despite this correction, consumption is still more volatile than output. In developed countries, typically consumption is significantly less volatile than output (see Baxter and Crucini, 1995).

[8]Recall that the parameter determining the adjustment cost of investment was chosen so that the model's prediction for the standard deviation of investment matches the observed one.

Table 4: Actual and Predicted Comovements
Sample: 1988:2 - 1994:3

	GDP_t	c_t	i_t	π_t	$\frac{tb_t}{GDP_t}$	rer_t

of alternative monetary policies that we present in the next section.

6 The welfare cost of dollarization

We are now ready to asses the welfare consequences of dollarization as compared to other possible monetary arrangements. We conduct the welfare analysis using the theoretical model developed in section 2 and calibrated in section 4. The sources of uncertainty driving business cycles are the three external shocks, terms of trade, import price inflation, and world interest rate, whose law of motion is estimated in section 3.

We measure the welfare costs of business cycles associated with a particular monetary policy regime by the fraction of nonstochastic steady-state consumption that households would be willing to give up in order to be indifferent between the corresponding constant sequences of consumption and hours and the equilibrium stochastic processes for these two variables associated with the monetary policy under consideration. Formally, letting c and h denote the nonstochastic steady-state values of consumption and hours and $\{c_t, h_t\}$ the equilibrium stochastic processes of consumption and hours corresponding to a particular monetary policy, we measure the cost of business cycles under such policy by the number ξ such that

$$U((1 - \xi)c, h) = E\{U(c_t, h_t)\},$$

where E denotes the unconditional mathematical expectation. According to this expression, the business cycles associated with a particular monetary policy are costly if ξ is positive and beneficial if ξ is negative. Following Lucas (1987), we approximate ξ by taking a second-order Taylor expansion of the above expression with respect to $(\ln c_t, \ln h_t)$ around $(\ln c, \ln h)$. In addition, we use the approximation $E \ln(y_t/y) = 0$ for $y_t = c_t, h_t$. Then, defining

$x_t = c_t^\nu (1 - h_t)^{1-\nu}$, ξ is given by

$$\xi = 1 - \left[1 + \frac{(1-\sigma)^2}{2} \mathrm{Var}(\hat{x}_t) \right]^{\frac{1}{\nu(1-\sigma)}}, \tag{45}$$

where, as explained earlier, a hat on a variable denotes its log-deviation from the nonstochastic steady state and $\mathrm{Var}(\hat{x}_t)$ denotes the unconditional variance of $\hat{x}_t$. Clearly, welfare costs are increasing in $\mathrm{Var}(\hat{x}_t)$. Table 5 presents the welfare costs associated with seven

Table 5: The welfare costs of Mexican business cycles under alternative monetary policy regimes

(Measured as percentage points of nonstochastic steady-state consumption)

Monetary Policy	Specification	Welfare cost
Dollarization	$\widehat{\epsilon}_t = 0$	0.27
Money growth rate peg	$M_t = (1 + \zeta) M_{t-1}$	0.17
Inflation targeting		
CPI inflation	$\widehat{\pi}_t = 0$	0.16
Nontraded inflation	$mr_t = mc_t$	0.18
Devaluation rate rule		
Constrained optimal	$\widehat{\epsilon}_t = -0.5\widehat{p}_t^x - 2.2\widehat{\pi}_t^{m*} + 26.1\widehat{r}_t^*$	0.01
Ad hoc	$\widehat{\epsilon}_t = -0.5\widehat{p}_t^x - 2.2\widehat{\pi}_t^{m*} + 2\widehat{r}_t^*$	0.15
Estimated Pacto policy	$\widehat{\epsilon}_t = \eta_t^\epsilon; \quad \sigma_{\eta^\epsilon} = 0.0145$	0.33

alternative monetary policies. The welfare costs are comparable across policies because all policies are specified in such a way that they give rise to the same nonstochastic steady state. The policies considered are those described in section 2.2.

The welfare gain of eliminating business cycles under the monetary policy in place during the Pacto era is 0.33 percent of steady-state consumption. This number is more than three times as large as the upper bound found by Lucas (1987) for the U.S. economy over the period following the Second World War. The welfare cost we find is comparable in magnitude to that reported by Lucas for the U.S. over the period prior to the Second World War. There are, however, two methodological differences between Lucas' calculations and ours. One is that Lucas uses actual data whereas we use data implied by a theoretical model. The other difference is that Lucas assumes that the single-period utility function depends on total

consumption whereas we assume that it depends on nondurable consumption and leisure. A problem in evaluating equation (45) using Mexican data is that until 1993 Mexico did not publish disaggregated consumption data and that no time series on hours worked is available. If one uses total consumption expenditures over the Pacto period and assumes that hours are constant, then one obtains a value of ξ of 0.51 percent. If instead one corrects the volatility of total consumption to proxy for the volatility of nondurables as described in section 5, then the value of ξ drops to 0.27 percent. Our model predicts a number that falls between these two figures.[9]
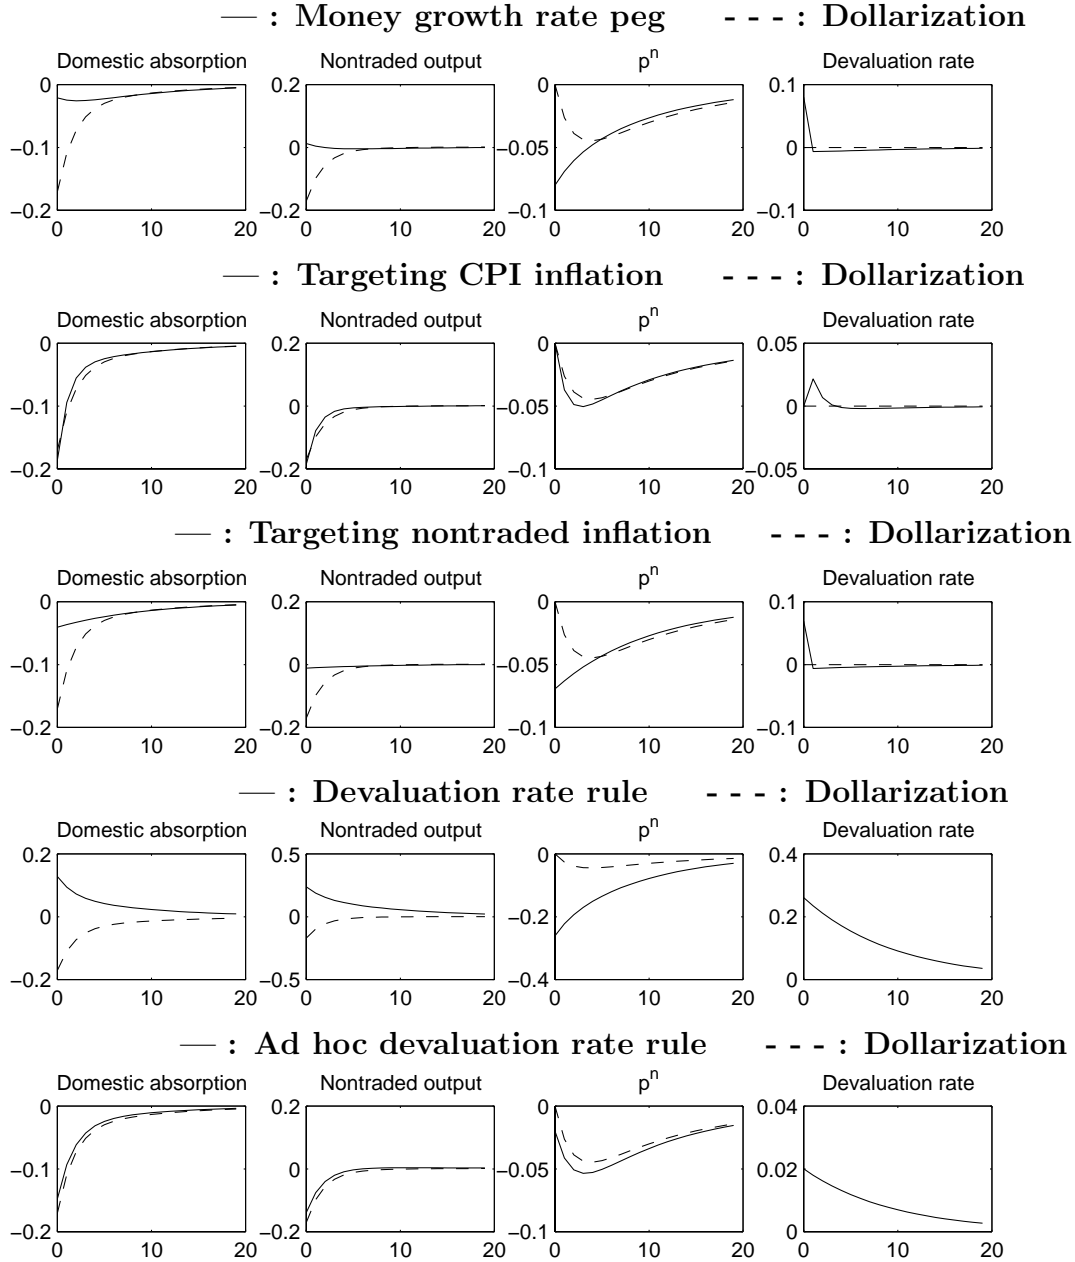

The main result that arises from the horse race presented in table 5 is that dollarization is welfare inferior to any of the alternative nonestimated policies considered. Households are willing to give up between 0.09 and 0.26 percent of their nonstochastic steady-state consumption to see a policy other than dollarization implemented.[10] The intuition behind this result is simple. Consider the effect of an increase in the world interest rate—the most important source of aggregate uncertainty in our model. In response to such a shock, aggregate demand falls. In a flexible price economy, the decline in aggregate demand would trigger a fall in the relative price of nontradables in terms of tradables. Under a fixed exchange rate, the nominal price of tradables cannot adjust. Thus, the decline in the relative price of nontradables would have to come about through a decline in the nominal price of nontradables. However, this price adjustment is not possible in the model studied here, because prices in the nontraded sector are sticky. The rigidity in the relative price of nontradables that arises from the combination of dollarization and nominal price stickiness exacerbates the contraction in the nontraded sector. It follows that if the monetary authority could respond to the adverse interest rate shock by devaluing the domestic currency, then the relative price of nontradables would be allowed to fall, making the adjustment of the sticky price economy more akin to that of a flexible-price economy.

A depreciation of the nominal exchange rate is precisely what happens under all of the alternative nonestimated monetary policies considered in table 5. This is the reason why these policies are associated with lower welfare costs than dollarization. We illustrate this intuition in figure 1, which shows the response of domestic absorption, nontraded output, the relative price of nontradables in terms of importables, and the devaluation rate to a percentage point increase in the world interest rate. To facilitate the understanding of the model's dynamics, the impulse responses are constructed assuming that the world interest rate follows a univariate AR(1) process with a serial correlation coefficient of 0.9. Each row compares the dynamic adjustment under dollarization (dashed line) with that under an alternative monetary policy (solid line). The impulse responses are expressed as percentage deviations from steady state.

---

[9]If one proxies hours worked by the employment rate for the population 12 years of age or older, then one finds a value of ξ of 0.45 percent using total consumption and 0.21 percent using our measure of nondurables. Because employment is typically less volatile than actual hours worked, all other things equal, it is likely to bias the welfare costs downward.

[10]Alternatively, the figures shown in table 5 can be interpreted as follows. The difference in the welfare cost of dollarization and that associated with another monetary policy indicates the fraction by which the sequence of consumption under dollarization would have to be increased in every period for agents to be indifferent between dollarization and the alternative monetary policy. For example, to make agents as well off under dollarization as under CPI inflation targeting, the stream of consumption in the dollarized economy would have to be increased by 0.11 percent at every date and state.

Figure 1: Model's response to a persistent world interest rate shock

— : Targeting nontraded inflation   - - - : Dollarization

— : Devaluation rate rule   - - - : Dollarization

— : Ad hoc devaluation rate rule   - - - : Dollarization

20

Consider, for example, the case of a money growth rate peg. The decline in aggregate demand induced by the interest rate hike produces a contraction in the demand for real balances. Given the supply of nominal balances, the adjustment in the money market must take place through an increase in the price level. Because the price of nontradables is sticky, the entire adjustment in the price level comes about via a depreciation of the nominal exchange rate. The mechanisms that lead to an initial depreciation of the nominal exchange rate under the other monetary policies considered are different but have an equally straightforward intuitive interpretation.

The best monetary policy specification considered is a devaluation rate rule of the form given in (28), where the coefficients were picked so as to minimize the welfare costs of business cycles. This is a 'constrained optimal' rule in the sense that it is the best within the class of devaluation rate rules that depend on $\widehat{p}_t^x$, $\widehat{\pi}_t^{m*}$ and $\widehat{r}_t^*$. The signs of the coefficients are what one would intuitively expect: the monetary authority devalues in response to a decline in the terms of trade, a decline in import price inflation, or an increase in the world interest rate. The intuition behind the benefits of such a devaluation rule should be clear from our above discussion regarding the real rigidity that dollarization introduces in our model. The constrained optimal devaluation rule calls for an extremely aggressive response of the devaluation rate to changes in the world interest rate. When the world interest rate increases by one percentage point, the devaluation rate is jacked up by 26 percentage points. This "hyperactive" policy stance, though optimal, seems implausible. Thus, we include in table 5 an ad hoc rule that maintains the coefficients on p^x and π^{m*} prescribed by the constrained optimal rule, but assigns a much smaller, and conceivably more implementable value of 2 to the interest rate coefficient. In this case the welfare cost of business cycles is still significantly smaller than that under dollarization and comparable to that associated with inflation or money growth targeting.

Finally, we note that the monetary policy that eliminates all inefficiencies stemming from sluggish price adjustment in the nontraded sector, namely, nontraded inflation targeting, has higher welfare costs than several of the other policies considered. Under this policy, marginal revenue equals marginal cost at all times. Thus, the economy behaves just like an economy without sticky prices. The reason why this policy does not have the lowest welfare costs is that while it eliminates the distortions associated with sluggish price adjustment it fails to neutralize the other distortions of the model that stem from the demand for money and the imperfectly competitive nature of the nontraded goods industry.

We wish to close this section with a word of caution. The welfare cost estimates presented are based on second-order approximations to the utility function and first-order approximations to the decision rules. As illustrated by Kim and Kim (1998) in certain economic environments such approximation is invalid and may indeed lead to spurious welfare rankings. It is therefore safer to interpret the results of this section simply as an investigation into the ability of the alternative monetary arrangements to reduce the volatility of x_t, the argument of the single-period utility function.

7 Final Remarks

In the welfare comparisons presented in this paper, the government is assumed to be able to perfectly commit to the implementation of any of the monetary policies considered. Our results may therefore be regarded as naive. After all, the reason why many observers favor dollarization is its assumed ability to tie the hands of governments too weak to resist the temptation of the printing press. However, the question of commitment could also be turned around: Is it not naive to believe that a chronically indisciplined government would alter its behavior merely because of a change in currency? Would such a government not simply get rid of dollarization at the first strong desire to inflate? Alternatively, would a government that has solved its fundamental fiscal problems not be as prepared to stick to dollarization as to any other low-inflation monetary policy? Clearly, these are issues that have yet to be explored, both empirically and theoretically.

A natural and potentially fertile ground for understanding the nature of government commitment to dollarization is monetary and fiscal behavior at the provincial level. To a large extent, a national currency is to a province what the U.S. dollar is to a dollarized country. In developing countries, the emergence of provincial money is not a rare phenomenon. For example, because the Argentine peso is legal tender in Argentina, its provinces can be considered "pesoized" economies. However, over the last two decades, a number of provincial governments in the northwestern region of Argentina have introduced local currencies. A case in point is the issuance of the CECOR in the province of Córdoba. In the mid 1990s, after having been hit hard by the Tequila effect, the government of Córdoba–the second most important province from an economic point of view after the province of Buenos Aires—was in financial dire straits. Having failed to meet wage payments for a number of months, the provincial government was facing an economic crisis of major proportions, which was threatening to degenerate into social chaos. As a way to circumvent its serious liquidity crunch, the government of Córdoba decided to pay wages and other current financial obligations with a provincial bond called CECOR explictly issued for this purpose (Fig. 2).[11] As soon as the CECOR was introduced, it began to play the quintessential role of money: medium of exchange. The CECOR rapidly assumed money's other two classical functions of store of value and unit of account.

By putting the CECOR in circulation, the government of Córdoba was in effect abandoning a monetary arrangement that featured the peso as the only medium of exchange. A number of important lessons can be learned from the CECOR episode: (i) Deviating from dollarization is likely to occur at a point at which not only the government but also the public perceives the regime shift as beneficial. In Córdoba, the CECOR introduced much needed liquidity in the midst of an unprecedented credit crisis; (ii) Governments can reintroduce domestic currencies almost effortlessly and clearly do not need to create a central bank first. The most likely scenario is that the Treasury department will simply print low-denomination government bonds and use them to pay for current government expenditures. Thus, all that is needed is a printing press and some government obligations; (iii) A 'domestic' currency can circulate even if the foreign currency maintains its status as legal tender. Indeed, during

---

[11]CECORs (Certificados de Cancelación de Obligaciones de la Provincia de Córdoba) were issued as two-year bearer bonds denominated in pesos paying an annual interest rate of 12 percent. CECORs were issued in denominations as low as five pesos, which is the equivalent of five U.S. dollars.

Figure 2: The CECOR: How Córdoba abandoned pesoization

its existence, the CECOR was Córdoba's primary medium of exchange.

But perhaps the most important lesson that can be learned from experiences like the CECOR in Córdoba is that the superiority of adopting a foreign currency over other conventional monetary arrangements as a commitment mechanism should not be taken for granted.

Appendix

Estimate of the law of motion of the exogenous external shocks

The first three equations of the VAR system given in (44) are

$$
\mathbf{a}_{11} \begin{pmatrix} \widehat{p}_t^x \\ \widehat{\pi}_t^{m*} \\ \widehat{r}_t^* \end{pmatrix} = \mathbf{b}_{11}(L) \begin{pmatrix} \widehat{p}_{t-1}^x \\ \widehat{\pi}_{t-1}^{m*} \\ \widehat{r}_{t-1}^* \end{pmatrix} + \begin{pmatrix} \epsilon_t^{p^x} \\ \epsilon_t^{\pi^{m*}} \\ \epsilon_t^{r^*} \end{pmatrix}.
$$

Premultiplying by the inverse of the lower triangular matrix $\mathbf{a}_{11}$ yields

$$
\begin{pmatrix} \widehat{p}_t^x \\ \widehat{\pi}_t^{m*} \\ \widehat{r}_t^* \end{pmatrix} = \mathbf{a}_{11}^{-1} \mathbf{b}_{11}(L) \begin{pmatrix} \widehat{p}_{t-1}^x \\ \widehat{\pi}_{t-1}^{m*} \\ \widehat{r}_{t-1}^* \end{pmatrix} + \mathbf{a}_{11}^{-1} \begin{pmatrix} \epsilon_t^{p^x} \\ \epsilon_t^{\pi^{m*}} \\ \epsilon_t^{r^*} \end{pmatrix}.
$$

The estimated coefficients of this system are presented in table A1. The regression includes, for each equation, a constant and a deterministic trend, whose estimates are not shown.

Table A1: Estimated law of motion of the external shocks

Quarterly data from 1987:Q1 to 1999:Q2

	$\widehat{p}_t^x$	$\widehat{\pi}_t^{m*}$	$\widehat{r}_t^*$
$\widehat{p}_{t-1}^x$	**0.5404**	0.0227	0.0004
$\widehat{p}_{t-2}^x$	**-0.4544**	-0.0355	-0.0046
$\widehat{p}_{t-3}^x$	0.2685	0.0364	-0.0003
$\widehat{p}_{t-4}^x$	**-0.3338**	-0.0019	0.0008
$\widehat{\pi}_{t-1}^{m*}$	-0.1278	0.2640	**0.0444**
$\widehat{\pi}_{t-2}^{m*}$	-0.2470	-0.2371	-0.0159
$\widehat{\pi}_{t-3}^{m*}$	1.4127	-0.1702	0.0174
$\widehat{\pi}_{t-4}^{m*}$	**-2.0365**	0.0256	0.0007
$\widehat{r}_{t-1}^*$	13.5131	0.6295	**1.4178**
$\widehat{r}_{t-2}^*$	-14.5399	1.4187	-0.4831
$\widehat{r}_{t-3}^*$	1.3230	-3.2075	0.0427
$\widehat{r}_{t-4}^*$	5.6132	0.2461	-0.0307
$\epsilon_t^{p^x}$	1	0.0515	0.0035
$\epsilon_t^{\pi^{m*}}$	0	1	0.0596
$\epsilon_t^{r^*}$	0	0	1
$\bar{R}^2$	0.54	0.45	0.96
D.W.	2.13	1.93	1.92
Nobs.	50	50	50

Note. Bold face indicates that the coefficient estimate is significant at the 10 percent level. $\widehat{p}_t^x$ denotes the log-deviation of the terms of trade from trend, $\widehat{\pi}_t^{m*}$ denotes log-deviation of gross import price inflation from trend, and $\widehat{r}_t^*$ denotes the log-deviation of the gross yield on 3-month U.S. Treasury bills from trend. The standard deviations of $\epsilon_t^{p^x}$, $\epsilon_t^{\pi^{m*}}$, and $\epsilon_t^{r^*}$ are, respectively, 0.0343, 0.0045, and 0.0006.
